1 **ABSTRACT**

2 Emission reduction strategies are gaining greater attention to support the national objective for a
3 sustainable and green transportation system. A large percent of emission contribution is from
4 transportation modes, primarily from auto and truck travel. Reductions in highway travel require
5 prudent planning strategies and modeling user's response to planner's policies. Modeling
6 planning goals and user's response is a challenging task. In this paper the authors present a joint
7 travel demand and environmental model to incorporate vehicle emission pricing (VEP) as a
8 strategy for emission reduction. First, the travel demand model determines the destination, mode
9 and route choice of the user's in response to the VEP strategy set by the planner. Second, the
10 emission model provides NO_x, VOC, and CO₂ estimates at a very detailed level. A Base-case
11 and three models are proposed to incorporate VEP in a multimodal transportation network. The
12 objective function of the Base-case is the minimization of Total System Travel Time (TST), and
13 the models are designed with objective of minimizing of Total System Emission (TSE). User
14 Equilibrium method is used in the demand model to model user responses and solved by Frank
15 Wolfe algorithm. The Base-case represents "do-nothing" conditions and the three models address
16 the interactions between planner's perspectives and user responses to VEP strategies. The
17 proposed model is applied to Montgomery County's (located in the Washington DC-Baltimore
18 region) multimodal transportation network. The case study results show that VEP can be used as
19 a tool for emission reduction in transportation planning and policy.

20 Key Words: Emission pricing, travel demand, multimodal, user equilibrium, frank wolfe

22 **INTRODUCTION**

23 In the United States (U.S) autos and trucks generate 25 percent of CO₂ emissions and account for
24 over 70 percent of its petroleum consumption (1). It is a surmountable task to achieve reductions
25 in greenhouse gases and ozone creating compounds to sustainable levels . Federal and state
26 agencies aim to minimize harmful effects of transportation on the environment to achieve
27 greenhouse gas and ozone targets. In particular, an explicit consideration is given to reducing
28 levels of NO_x, VOC (ozone creating compounds) and CO₂ (greenhouse gas) through better
29 operational level planning. Measuring and reducing emissions requires quantification in
30 modeling activities and incorporation into planning methods. The choice of type and nature of
31 emission functions are important for deriving accurate estimates in the planning of transportation
32 activities. Currently, there are two types of feasible methods, one is a long-term solution to
33 improve public transport such that the mode shift can cause a large emission reduction and the
34 other is a short-term solution to influence traveler behavior by imposing vehicle emission pricing
35 (VEP) such that there are minimal emissions produced in the system (2). Although the former is
36 the ideal scenario, for a long-term sustainable solution, the later needs more careful analysis
37 before determining additional cost to the user to achieve substantive emission reductions. In both

1 cases there is a need for the development of travel demand or behavioral models. Such models
2 are capable of examining the travel behavior of road users and their responses to impedances
3 such as VEP to achieve emission reductions. In this context, VEP can be used a tool to model
4 traffic flows in a transportation system, by choosing an alternate route, being elastic to travel
5 options or a combination of both.

6 In this paper, we propose a joint travel demand (called a demand model, hereafter) and
7 emission model to achieve emission reduction for the major pollutants NO_x, VOC, and CO₂. The
8 demand model incorporates individual travel behavior in determining travel choice and route
9 choice in response to emission pricing strategies set by the decision maker. The Environmental
10 Protection Agency (EPA) developed MOfor Vehicle Emission Simulator (MOVES) is integrated
11 with the demand model for estimation of pollutants. Developing such models is complex and
12 involves two major hurdles. First, the difficulty lies in obtaining specific and accurate emission
13 levels with which to model individual driver responses to examine how the targets are achieved.
14 Second, the application of these models in real world case studies to assist federal, state and local
15 agencies (or decision makers) to achieve emission reduction objectives.

16 The proposed methodology in the paper incorporates a VEP technique in a step by step
17 manner. In the next section a literature review is presented, followed by model formulation and
18 solution methodology. The case study section describes the overview of the region's geography,
19 and transportation network characteristics. Model application and scenario results are presented
20 in the next section. Finally, the conclusion section summarizes the findings, depicts contributions
21 of the paper and enumerates future scope of research.

22

23 LITERATURE REVIEW

24 Emission reduction strategies are well studied in the literature. In a decision making framework
25 these strategies can be viewed as a Stackelberg's game theory in bi-level modeling. The upper
26 level represents the decision maker's goal (or preference) based on a certain objective and the
27 lower level represents user's response (whether or not to follow) the upper level strategy. In
28 transportation engineering, the upper level can be considered the minimization of emission
29 through VEP and the lower level represents driver's response to the policy at the upper level
30 (3)(4). In some cases the upper level strategies are *a priori*, and exogenously defined and in others
31 the strategies are concurrently optimized in conjunction with the lower level. The lower level is
32 solved with the traffic assignment optimization problem, and the most common objectives are
33 the minimization of cost and time (5). Although in reality the two objectives are nearly identical,
34 as time is monetized in the assignment process, cost is considered a separate variable in order to
35 achieve positive externalities like fundraising or market based trip decision making. Uncommon
36 in the literature is the objective to minimize the environmental impacts of vehicular traffic
37 through a pricing mechanism (or derivatives thereof).

1 A number of studies have developed emission factors before applying them in the
2 assignment process. While factors may vary based on area type, speed, highway congestion,
3 weather conditions and other factors, use of these factors require a large amount of effort in data
4 collection. In addition, development of emissions factors requires a calibration process and may
5 not lead to an accurate estimation of emissions. The EPA MOVES model has been extensively
6 developed to measure emission factors for different regions in the U.S. While some researchers
7 point out a few limitations in models like MOVES (6), where there is a specialized need for
8 emissions modeling, for the purpose of this research design and other scenario-based research,
9 MOVES provides an excellent tool to measure changes in emissions based on changes traffic
10 demand, assignment and other network characteristics.

11 Several studies examine the relationship between network flow and system emissions
12 (3)(7). Effective modeling efforts have focused on incorporating road pricing into the highway
13 assignment algorithm via Waldrop's User Equilibrium (UE) objective function and a Frank-Wolf
14 (FW) solution approach (3). The results typically show that flow, as a function of link volume
15 and capacity, has a substantial impact on the overall level of emissions. However this is not the
16 only condition that potentially affects total emissions. Nagurney (7) points out several conditions
17 which can produce increased network emissions which include (somewhat paradoxically) the
18 addition of a link, a decrease in travel demand and improvements in link cost structure (i.e. travel
19 on the link becomes cost effective). The results of the study point out that a reduction in
20 emissions requires not only improvements to network flow, possibly through demand
21 management (8)(9), but also with the addition of supply side management, most feasibly in the
22 form of a VEP.

23 The most efficient and equitable method to achieve substantive reductions in vehicle
24 emissions is through a pricing mechanism ((10), (11)). Previous studies show that pricing can
25 have substantial impacts depending on the policy objective, particularly in terms of internalizing
26 the negative effects of emissions and for the market effect of pricing on trip, mode and route
27 choice (12). An effective emission pricing strategy requires a large enough network to provide
28 alternative routes and links with low enough saturation to absorb additional volume in order to
29 show significant emissions improvement (13). An effective pricing strategy is therefore one that
30 either prices links in a given area (such a non-attainment area) or along a single corridor. On the
31 other hand, in the absence of viable route and link alternatives a mix of pricing and demand
32 elasticity, which is the assumption that at the right price some trips will not occur or travelers
33 will switch modes, can be used to effectively reduce TSE ((4),(12), (14), (15)).

34 Therefore the application of VEP strategy should be incorporated for emission
35 minimization to examine the interaction between decision maker's policy and the user's
36 response. Application of VEP strategies for real world conditions is limited in the literature. This
37 paper analyzes a Base-case depicting existing emission levels, and proposes a set of models to
38 minimize emissions in a combined framework of user's response to decision maker's policies.
39 The framework consists of a joint travel demand and emission model to incorporate VEP

- 1 strategies for emission minimization. In the remainder of the paper emission pricing and VEP is
 2 used interchangeably. The next section describes the model formulation. The notations for model
 3 formulation are presented below.

Notation	Explanation
\hat{d}_{ij}^φ	: Potential demand between i - j
Φ_a	: Emissions cap for each link a
AOC_m^p	: Auto operating cost for mode m and purpose p
C_a	: The capacity for link a
C_{jn}	: Correction term to compensate for sampling error in model estimation
DA_m^p	: Drive access time for mode m and purpose p
D_{ij}^{-1}	: The inverse demand function associated with O-D pair i - j
D_{ij}^k	: Various distance terms (linear, log, squared, cubed and square root)
E_j^k	: Employment of type k in zone j
$IVTT_m^p$: In-vehicle travel time for mode m and purpose p
$IWTA1_m^p$: Initial waiting time less than 7.5 minutes for mode m and purpose p
$IWTb_m^p$: Initial waiting time greater than 7.5 minutes for mode m and purpose p
L_{ij}	: The mode choice logsum between zone pair ij
NOT_m^p	: Number of transfers for mode m and purpose p
N_n^k	: Person, household or production zone characteristics for trip n
PC_m^p	: Parking cost for mode m and purpose p
S_j	: Size variable for destination zone j
TET_m^p	: Terminal time for mode m and purpose p
TF_m^p	: Transit fare for mode m and purpose p
U_{ijn}	: The utility of choosing a trip attraction destination j for a trip n produced in zone i
U_m^p	: Utility function for auto and transit travel
WT_m^p	: Waiting time for mode m and purpose p
Z_j^k	: Attraction zone characteristics
$d_{ij}^\varphi(x_{ij})$: New demand between O-D pair i - j
e_a	: Emission price
e_a^l	: Emission pricing for link in the corridor
e_b	: Total corridor emission price
f_{ij}^r	: Flow on path r , connecting each Origin-Destination (O-D) pair (i - j)
l_a	: Distance for link a
l_b	: Length of the corridor
q_{ij}	: Demand between each Origin-Destination (O-D) pair (i - j)
t_a	: Travel time for link a
$t_a(x_a)$: Travel cost on link a as a function of flow
u_a	: User cost for link a
$u_a^l(x_a, e_a)$: Travel time function for Model-1 which incorporates emission pricing term e_a
u_{ij}^c	: Least cost path between O-D pairs i - j
x_a	: Flow for link a
α_a	: Constant, varying by facility type (BPR function)

β_a	:	Constant, varying by facility type (BPR function)
β^k	:	Weights for each term in the size variable (S_j)
γ^c	:	Value of time (VOT) for user class c
$\delta_{a,ij}^r$:	Flow on link a , a subset of path r , connecting each Origin-Destination (O-D) pair (i - j)
π_m^p	:	Mode specific constant for mode m and purpose p
τ_a	:	Toll value for link a
ϕ_a	:	Total emissions for link a
c	:	User class
t_o	:	Free flow time on link a
β	:	Mode and attribute specific coefficient (mode choice model)
φ	:	Factor to convert emission price to travel time units
ω	:	A positive constant (exponential demand function)
n	:	Assignment iteration number

1

2 **MODEL FORMULATION**

3 In this section the Base-case (do-nothing) and three different models incorporating optimal
4 emission pricing are presented. Each section describes the model formulation and the appropriate
5 need for decision making.

6

7 **Base-Case**

8 The base case represents “do-nothing” or current conditions without any VEP. The user behavior
9 is studied in the trip assignment stage and is solved by classical user equilibrium method (5).

$$\text{Minimize } \sum_a \int_0^{x_a} \left(t_a(x_a) + \frac{\tau_a(x_a)}{\gamma^c} \right) \quad (1)$$

10 subject to:

$$\sum_r f_{ij}^r = q_{ij} \quad (2)$$

$$x_a = \sum_i \sum_j \sum_r f_{ij}^r \delta_{a,ij}^r \quad (3)$$

$$f_{ij}^r, q_{ij}^r \geq 0 \quad (4)$$

11 The objective function shows minimization of TST of the network as per Wardrop's first
12 principle, which denotes that “no user can experience a lower travel time by unilaterally
13 changing routes” (16). In simple terms the equilibrium is achieved when the travel cost on all

1 used paths is equal. The three terms in equation (1) represent the total travel cost. The first term,
 2 t_a , is the travel time for link a , which is a function of link flow x_a . The second term, τ_a is the
 3 toll value for link a . The toll value is converted to units of time by considering the value of time
 4 (VOT) for c user classes. Realistically, VOT varies by user class. This term is included to
 5 incorporate the differential effect of toll roads (if a toll road exists in the network, zero
 6 otherwise), on travel costs for each class of users. The sum of these two terms in Equation (1)
 7 can be referred as user cost for link a ($u_a = t_a(x_a) + \frac{\tau_a(x_a)}{\gamma^c}$). Equation (2) is a flow conservation
 8 constraint to ensure that flow on all paths r , connecting each Origin-Destination (O-D) pair ($i-j$)
 9 is equal to the corresponding demand. In other words, all O-D trips must be assigned to the
 10 network. Equation (3) represents the definitional relationship of link flow from path flows.
 11 Equation (4) is a non-negativity constraint for flow and demand. The travel time function $t_a(\cdot)$ is
 12 specific to a given link ' a ' and the most widely used model is the Bureau of Public Roads (BPR)
 13 function given by

$$t_a(x_a) = t_o \left(1 + \alpha_a \left(\frac{x_a}{C_a} \right)^{\beta_a} \right) \quad (5)$$

14

15 where $t_o(\cdot)$ is free flow time on link ' a ', and α_a and β_a are constants (and vary by facility
 16 type). C_a is the capacity for link a . In the base model the objective is minimization of total
 17 system travel time. Emission is not a component of the base case. The emission parameters are
 18 derived from MOVES and utilized exogenously to the assignment method for the Base-case.

19 When the objective function is expanded to include the minimization of TSE, the
 20 emission model is moved into the assignment program. After the initial iteration of assignment,
 21 based on free-flow travel time, the resulting emissions are calculated using the MOVES model
 22 derived emissions factors. The factors used are based on link speed, volume, distance, time of
 23 day, facility type and area type. The pre-determined emissions cap is then subtracted from the
 24 newly calculated emissions which becomes the basis for the emissions charge at the end of each
 25 assignment iteration.

26 **Model-1: Link Based Emission Pricing**

27 When the decision maker has the objective to minimize total emission, link based emission
 28 pricing may be the first option. Based on a policy criteria such as links exceeding a threshold
 29 emission value need to be priced. The threshold value can be considered as an emission cap. The
 30 cap can be determined by calculating the link level emissions for the entire network in the base
 31 year by grams per mile for each link. The cap can be then set at the average of emissions per
 32 mile. The cap for each link can then be determined by multiplying the average grams of
 33 emissions per mile by the distance of each link. The emissions cap for each link is:

$$\Phi_a = \left[\frac{1}{N} \sum_{a=1}^N \left(\frac{\phi_a}{l_a} \right) \right] * l_a \quad (6)$$

1 where ϕ_a is the total emissions for link a calculated for each link in the base model and
 2 l_a is the link distance. Once the cap is determined, the emission price (e_a) can be incorporated
 3 into the travel demand model. The emission price can be converted to travel time units with
 4 appropriate factor (φ) representing VOT in monetary terms. The revised user cost function for
 5 link based emission is

$$u_a^l(x_a, e_a) = t_a(x_a) + \frac{\tau_a(x_a)}{\gamma^c} + \frac{\varphi e_a(x_a)}{\gamma^c} \quad (7)$$

6
 7 where $u_a^l(x_a, e_a)$ is the travel time function for Model-1, which incorporates emission
 8 pricing term e_a . The objective function for Model-1 is similar to base case with the exception
 9 that the third term from equation (7) ($\frac{\varphi e_a(x_a)}{\gamma^c}$) is added to equation (1). The emissions price for
 10 each link is updated at the end of each assignment iteration based on the emissions produced as a
 11 result of that assignment over the predetermined cap, so that changes in the results of each
 12 assignment are reflected in the travel cost faced by each user which like travel time, will vary
 13 between assignment iterations. It should be noted that with the revised user cost function the
 14 objective of Model-1 is to minimize total system emission (TSE) as opposed to the Base-case
 15 where the objective was to minimize total system travel time (TST)

16

17 **Model-2: Corridor Based Emission Pricing**

18 Link based emission pricing provides overall estimates of the user behavior responses to a
 19 predefined threshold value. However, pragmatically it may be difficult to implement link based
 20 emission pricing. As a revised approach, emission pricing can be applied to corridors (set of
 21 contiguous links) instead of individual links. The difficult part is to determine which corridors
 22 need to be priced. The threshold value for corridor can be determined as follows.

$$\Phi_b = \sum \left[\frac{1}{N} \sum_{a=1}^N \left(\frac{\phi_a}{l_a} \right) \right] * l_a \quad (8)$$

23 where ϕ_b is the total emissions for corridor b , calculated for each link in the base model
 24 and l_a is the link distance. Similar to equation (7) emission pricing for the corridor e_b can be
 25 incorporated into the user cost function. However implementation of corridor based emission
 26 pricing may be difficult in a demand model. Alternatively, the total pricing for a corridor can be

1 proportionally attributed to each link of the corridor. The emission pricing for link in the corridor
 2 (e_a^l) can be obtained by the following equation.

$$e_a^l = \left(\frac{e_b}{l_b}\right) l_a \quad (9)$$

3

4 where e_b is the total corridor emission price, l_b is the length of the corridor, and l_a is the
 5 length of link a . Similar to the pricing method in Model-1, the corridor emission price is
 6 determined at the end of each assignment iteration, based on the amount of emissions produced
 7 on the corridor over the cap for each iteration of the assignment model.

8 **Model-3: Variable Demand Emission Pricing**

9 Both link (Model-1) and corridor based emission pricing (Model-2) provide a good
 10 understanding of shifting routes and modes (discussed later in the paper) to minimize total
 11 system emission. These models will be very helpful to analyze the reduction of emissions as a
 12 result of VEP. However, both Model-1 and Model-2 do not consider the variability of demand
 13 because of changes in network conditions as a result of vehicle emission pricing. Alternatively,
 14 the users are not elastic to the emission pricing strategy. Demand elasticity can be incorporated
 15 to the base case by introducing inverse demand function in the objective function. Modeling
 16 variable demand completely changes the objective function. This can be represented as follows.

$$\text{Minimize } \sum_a \int_0^{x_a} \left(t_a(x_a, e_a) + \frac{\tau_a(x_a)}{\gamma^c} + \frac{\varphi e_a(x_a)}{\gamma^c} \right) - \sum_{ij} \int_0^{q_{ij}} D_{ij}^{-1}(x_a, e_a) \quad (10)$$

17

18 This formulation allows the decision maker to model the elasticity of the user behavior.
 19 The constraints for the variable demand model remain same as in the base case (see equations 2-
 20 4). The inverse demand function $D_{ij}^{-1}(\cdot)$ is associated with O-D pair $i-j$. An exponential demand
 21 function is then used which is a function of potential demand and least user cost paths to
 22 determine the new demand $d_{ij}^\varphi(x_{ij})$ between O-D pairs is given by

$$d_{ij}^\varphi(x_{ij}) = \hat{d}_{ij}^\varphi \exp(-\omega * u_{ij}^c) \quad \forall i, j, \tau \quad (11)$$

23 where \hat{d}_{ij}^φ is the potential demand between $i-j$, u_{ij}^c is the least cost path between O-D
 24 pairs $i-j$ and ω is a positive constant. This new demand is then fed back into the highway
 25 assignment model. The users in the $i-j$ O-D pair are now elastic to the cost of travel (u_{ij}^c).
 26 Alternatively, as the cost increases the willingness to travel decreases. The emission cap for this
 27 case can be at the discretion of the decision maker. Link based or corridor based emission pricing
 28 can be incorporated into the variable demand model (equation 6, and 8).

1

2 **Destination and Mode Choice**

3 The assignment procedure for the base case and three models are explained in the earlier section.
 4 The demand model should also be sensitive to the destination and mode choice as the network
 5 characteristics change. The following section describes steps on how destination choice and
 6 mode choice are implemented in the demand model. The utility U_{ijn} of choosing a trip attraction
 7 destination j for a trip n produced in zone i is given by:

$$U_{ijn} = S_j + \alpha L_{ij} + \sum \beta^k D_{ij}^k + \sum \beta^k D_{ij}^k N_n^k + \sum \beta^k Z_j^k + C_{jn} \quad (12)$$

8 Where, S_j is the size variable for destination zone j , L_{ij} is the mode choice logsum
 9 between zone pair ij , D_{ij}^k represents the various distance terms (linear, log, squared, cubed and
 10 square root), N_n^k represent person, household or production zone characteristics for trip n and is
 11 used for creating interaction variables with distance terms, Z_j^k represents attraction zone
 12 characteristics (other than the size term), and C_{jn} is a correction term to compensate for the
 13 sampling error in the model estimation (i.e., it represents the difference between the sampling
 14 probability and final estimated probability for each alternative). The size variable may consist of
 15 several different terms; up to four categories of employment in addition to households were used.
 16 Weights (β^k) for each term in the size variable were estimated along with all other model
 17 parameters as follows, where E_j^k is employment of type k in zone j :

$$S_j = \log \left(\sum \beta^k E_j^k \right) \quad (13)$$

18 The destination choice model provides O-D demand for all trip purposes. A nested logit structure
 19 is formulated for mode choice, which is based on generalized utility functions for auto and transit
 20 travel. Separate utilities were developed to represent mode choice by trip purpose and time of
 21 day. The mode choice utility function is represented as follows:

22 The complete utility function for mode choice is as follows:

$$U_m^p = \pi_m^p + \beta_{1m}^p IVTT_m^p + \beta_{2m}^p TET_m^p + \beta_{3m}^p \times AOC_m^p + \beta_{4m}^p PC_m^p + \beta_{5m}^p \tau_m^p \\ + \beta_{6m}^p WT_m^p + \beta_{7m}^p IWTa1_m^p + \beta_{7m}^p IWTb_m^p + \beta_{8m}^p NOT_m^p \\ + \beta_{9m}^p TF_m^p + \beta_{10m}^p DA_m^p \quad (14)$$

23 Where π_m^p is a mode specific constant for mode m , and purpose p ; β in each term is the
 24 mode and attribute specific coefficient; $IVTT$ is the in-vehicle travel time, TET is the terminal
 25 time, AOC is the auto operating cost, PC is the parking cost; τ is the toll value, WT is the
 26 waiting time, $IWTa$ is the initial waiting time less than 7.5 minutes; $IWTb$ initial waiting time
 27 greater than 7.5 minutes; NOT is the number of transfers, TF is the transit fare; and DA is the

1 drive access time. The mode choice model results in splitting O-D trip matrices into 11 travel
2 modes (3 auto modes, and 8 transit modes). Three auto modes refer to Single Occupant Vehicles
3 (SOV), High Occupant Vehicles with 2 occupants (HOV-2), and High Occupant Vehicles with
4 three or more occupants (HOV-3+). Eight transit modes are walk and drive to bus, express bus,
5 rail, and commuter rail.

6

7 **SOLUTION METHODOLOGY**

8 Figure 1 shows a flowchart of the solution algorithm for both the Base-case and the three
9 emissions models. The algorithm relies first on inputs commonly found in demand models,
10 which includes the characteristics of the transportation networks (highway and transit), socio-
11 economic and other inputs needed for the trip generation, destination choice, mode choice and
12 traffic assignment programs. The traffic assignment is solved with a FW algorithm. In the FW
13 when the model has met the convergence criteria, the next model begins by running the first
14 group of programs in the emissions model to setup the emissions inventory derived from the
15 Base-case. The objective of the Base-case is minimization of TST. The algorithm then diverges
16 to run Model-1, Model-2 or Model-3 (with objective of TSE). If the shortest emissions path is
17 selected, the model performs the first iteration of the Model-1/ Model-2 modified assignment
18 with the emissions minimization function. After the first iteration the model checks for
19 convergence then recalculates emissions based on that iteration's assignment results. The
20 iterative procedure between assignment and emissions algorithms continues until the results meet
21 the convergence criteria.

22 For Model-3, variable demand is calculated based on the least cost path. The variable
23 demand model first skims the Base-case assigned network for congested travel times. The
24 shortest path between all O-D pairs is calculated and used in the inverse demand function to
25 calculate the new demand based on the shortest path. Once the new demand is calculated it is
26 used in the assignment model. The assignment model then iterates between the emissions model
27 and assignment until the convergence criteria for the assignment program is met. Once the
28 assignment convergence is met the nearest shortest path from the equilibrium assignment, the
29 demand for the next iteration is determined. The model iterates between emissions minimization
30 assignment and variable demand until the model converges. The complete model structure is
31 incorporated into the transportation planning software, Cube Voyager (17). The UE assignment
32 algorithm is also modified in Cube Voyager to reflect VEP for all three models. A brief
33 description of the step by step approach is shown in Appendix-A.

34

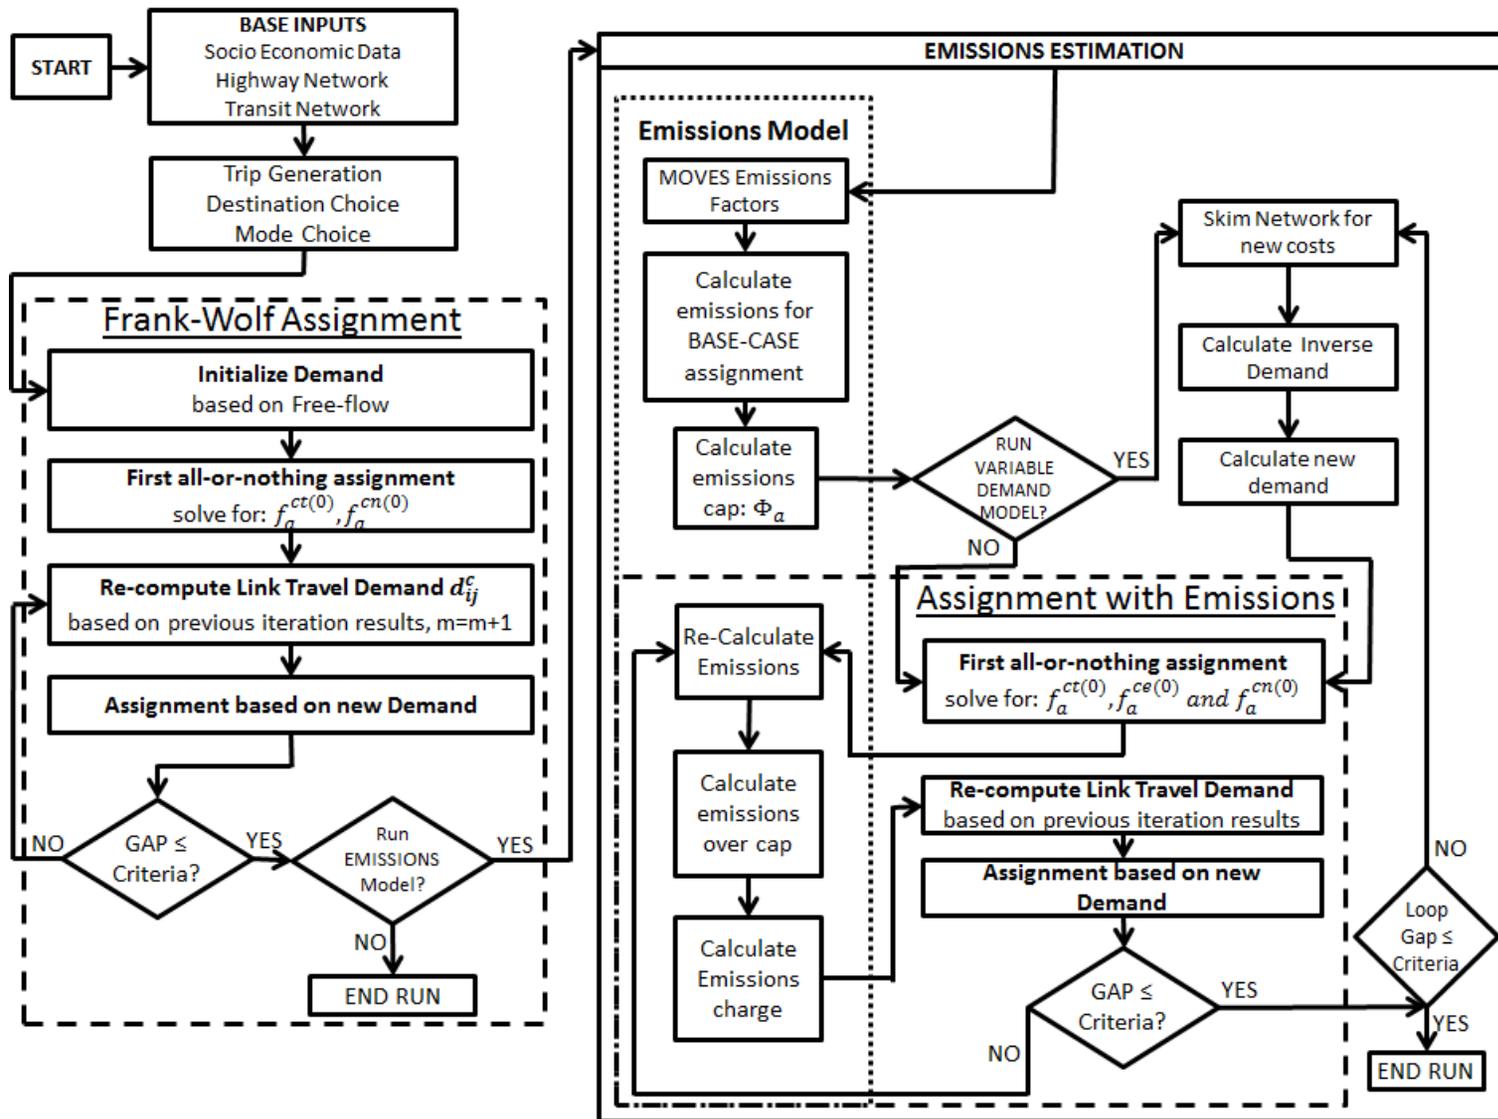

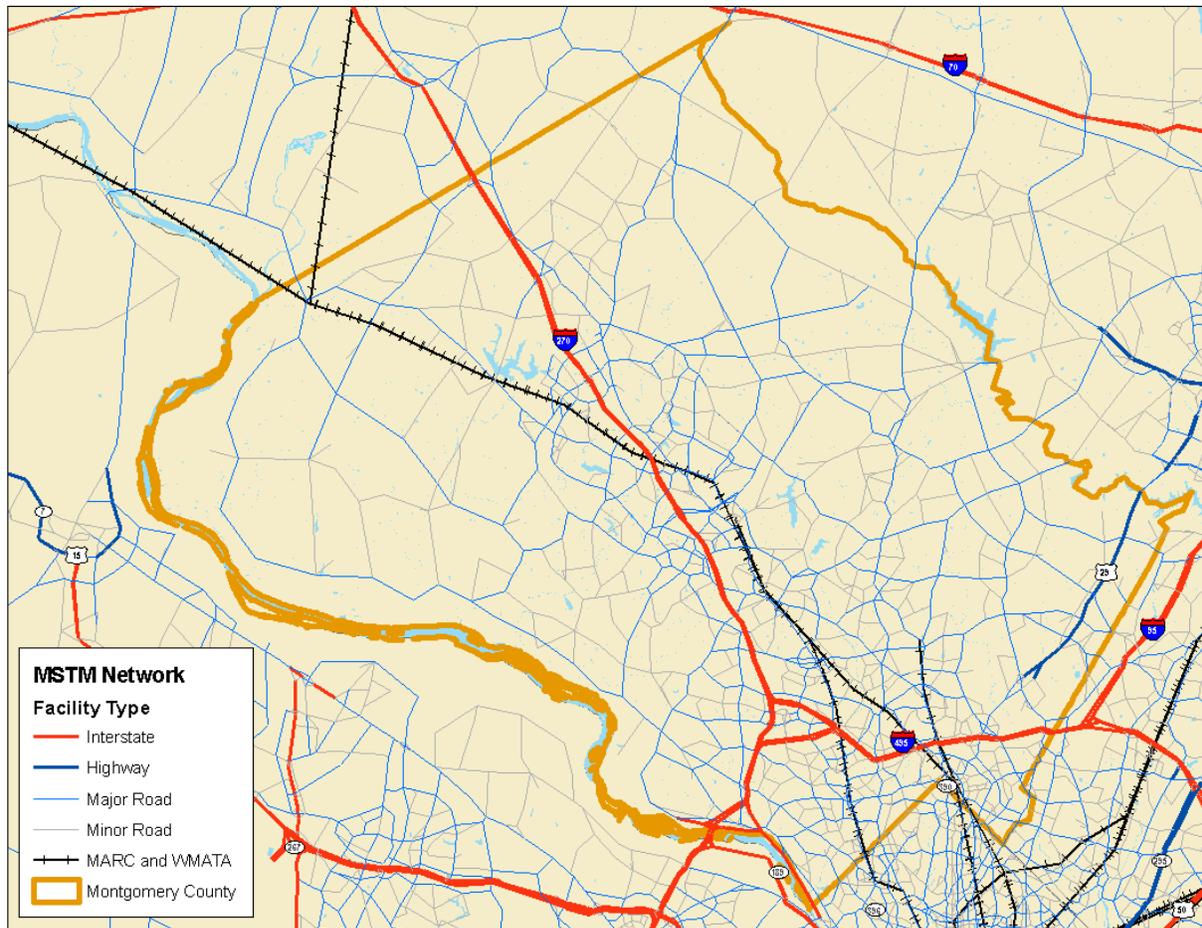

FIGURE 1 Solution Methodology

1 CASE STUDY

2 The proposed framework is applied to Montgomery County in Maryland. Montgomery is the
 3 most populous county in the state with a population close to one million, 400,000 households,
 4 and employment of 600,000. The county boundary with the transportation network is presented
 5 in Figure 2. The county contains parts of the heavily travelled roadways in the Washington DC-
 6 Baltimore region (Washington DC is referred to as Washington in the remainder of the paper).
 7 The county has an extensive highway network with the Capital Beltway (or Interstate-495), that
 8 surrounds Washington, passing through Montgomery County. Interstate-270 interstate forms one
 9 leg of an interstate triangle between Washington DC, Baltimore city and Frederick city. The
 10 county also contains a portion of route 29, one of the major state routes, which run between the
 11 Washington and Baltimore beltways. In terms of transit, the commuter rail MARC, which travels
 12 between Brunswick (North) to Union Station (South), travels completely through Montgomery
 13 County. A major metro line (called the Red Line) also travels through the county. In addition,
 14 Washington Metropolitan Transit Authority (WMATA) provides bus service and the county has
 15 extensive coverage of its own bus system called "RIDE-ON" with very high capacity and
 16 frequency.

17

18 **FIGURE 2 Montgomery County Transportation Network**

1
2 There are a total of 4,302 highway links in Montgomery County consisting of all facility types
3 representing a total of 3,630 lane miles. In addition, the network consists of 73 bus lines. A
4 number of transit options are available in the network. Montgomery county has an extensive
5 continuous emission monitoring (CEM) program and the mission is to examine emission
6 reduction strategies. This paper is geared towards this mission to propose a number of emission
7 reduction strategies by using travel demand and emission models. However, the proposed
8 methodology can be extended to other regions.

9

10 **MODEL APPLICATION**

11 The Montgomery county study area consists of 223 zones and 49,729 O-D pairs. The data is
12 obtained from the Maryland Statewide Transportation Model developed by The Maryland State
13 Highway Administration. The population, households (by size and five income categories), and
14 employment (four industry categories) are used for trip generation purposes. The destination
15 choice model adequately distributes the trips between O-D pairs as per the formulation presented
16 in Equation (12). Further, the mode choice model splits between autos and transit. Additionally,
17 the assignment process provides the shortest user cost paths to the O-D pair and represents user's
18 response. Details of trip generation, destination and mode choice are not presented in the paper
19 for brevity and much emphasis is given to highway assignment. The model application section
20 consists of results from the Base-case, and three models.

21 The summary of results is presented in Table 1. The first column shows the four cases
22 analyzed. Further, for each case, the emission results from four facility types are presented. For
23 Base-case and for each model the emissions in terms of NO_x , VOC and CO_2 are shown in
24 column (3), (4), and (5). In the Base-case, the objective is to minimize total system travel time
25 (TST); the effect of the final assignment on total emissions was ignored by the assignment
26 algorithm to satisfy the very purpose of the Base-case which is estimating emissions and not to
27 apply VEP. Emissions are estimated after the traffic assignment stage. The freeways from Base-
28 case resulted in 8.7 million grams of NO_x , 1.1 million grams of VOC, and 1,877 million grams of
29 CO_2 . Among all facilities in the base case, freeways produce the largest amount of emissions. A
30 total of 1,887 million grams of emissions resulted from the Base-case. A pictorial representation
31 of link-based emission is shown in Figure 3(a). Interstates 495 and 270 are the highest
32 contributors of total emissions. Other areas of concern are along route 29 (lower right corner
33 going north/south) and Connecticut/Georgia avenues (orange links crossing I-495) which are all
34 heavily travelled corridors.

35 For Model-1, a threshold value or emission cap is determined (please see equation (8)),
36 however the VEP is based on the total amount of emissions that exceed the cap after each
37 iteration of the assignment program, meaning the links to be priced and the amount of the VEP

1 (e_a) changes with the iterative change in link flow (x_a). From the Base-case emission results, the
 2 50th percentile of emissions in grams per mile is determined. The links over the emission cap are
 3 subjected to VEP in Model-1. The emission cap is estimated as \$0.0006 per gram (or \$60 per
 4 tonne) of emissions for travel on links that exceed a predefined emissions cap of 435 thousand
 5 grams per mile resulting from the emissions inventory from the Base-case. The assignment
 6 algorithm seeks to minimize TSE. Model-1 produces a substantial level of emission reduction
 7 resulting in total emissions of 1,433 million grams, and 6.4 million grams NO_x, 0.9 million grams
 8 VOC, and 1,426 million grams of CO₂ (Table 1). This amounts to a little over 24% reduction in
 9 all emissions. Among the facility types, freeways are still the major contributor (considering the
 10 dominate flow pattern over other facility types) but exhibit the largest reduction (44%) in
 11 emissions.

12 Figure 3(b) presents a map of link emissions in the study area. While Model-1 results in
 13 emission reductions, the difficulty in implementing enforcement policy, and the effect it has on
 14 non-charged areas outside Montgomery County and the impact on local roads that are able to
 15 absorb more emissions due to lower activity levels in the base model, would make this a difficult
 16 emissions pricing strategy. With new technologies such as GPS tracking and electronic pricing, it
 17 is likely that such a strategy could be implemented, but we suggest more a traditional pricing
 18 method, by selecting a single heavily emitting corridor as opposed to a single link.

20

21

1 Model-2 represents the VEP for a single corridor. A corridor is selected where a set of
2 contiguous links over 10 miles produce link based emissions higher than the cap (set at 50% of
3 emissions per mile for link in the corridor in the Base-case). For the case study, an analysis of the
4 highway network showed that Interstate-270 is the only corridor to meet the criteria. However,
5 for a larger network, there can be multiple corridors, and the model can analyze such an effect.
6 Interstate-270 is a heavily used corridor for commuting between its terminus in Frederick
7 Maryland and Washington DC. Along this corridor are many densely developed areas in
8 Montgomery County. Emissions from this corridor alone account for over 17% of total vehicle
9 emissions in the Base-case. Model-2 imposes a charge of \$0.0006 per gram of emissions for
10 travel on links that exceed the predefined emissions cap of 1.2 million grams per mile resulting
11 from the emissions inventory from the Base-case. The VEP is only applied to the selected I-270
12 corridor. Table 1 shows that total emissions for Model-2 are 1,789 million grams with 8.0
13 million grams NO_x , 1.1 million grams VOC, and 1,780 million grams of CO_2 . As a result of the
14 corridor pricing strategy, the largest contributor of emissions switches to major arterials. This is
15 largely a result of users selecting alternative routes that are within Montgomery County but still
16 result in lower travel time. While Model-2 leads to an overall reduction in emissions of over 5%,
17 it results in increased emissions for all other facility types due to excess use which produces a
18 higher volume of trips and a greater number of congested lane miles increasing emissions on
19 major arterials by 18%, minor arterials 21% and other roads by 6.5%. Figure 3(c) shows the
20 results of Model-2 on emissions in the study area. The results show there is a substantial
21 improvement of generally over 50% reduction in emissions along the corridor. The figure also
22 shows the impact of VEP on a single corridor. Neighboring links become saturated with traffic
23 and emissions increase. However, these links are generally able to absorb enough extra volume
24 and emissions that TSE is reduced.

25 Model-3 represents variable demand conditions, modeling the elastic nature of travelers'
26 behavior to the given network conditions. When the VEP strategy is employed in the variable
27 demand model a number of users may first decide whether or not to make a trip subject to
28 imposed user costs. The "willingness to travel" was not analyzed in the earlier two models. For
29 the variable demand model, in equation (11) the value of ω is 0.01 representing the elasticity of
30 users response to travel cost (9). The total emissions from Model-3 resulted in 1,717 million
31 grams with 7.9 million grams NO_x , 1.0 million grams VOC, and 1,708 million grams of CO_2 . For
32 Model-3, a reduction in all pollutants for all facility types was achieved. The results show a
33 reduction of 9% in total emissions, falling between the Model-1 and Model-2 results. Users'
34 response to levels of congestion and VEP on the 270 corridor helped to improve emissions by
35 reducing the number of vehicle trips taken within the county.

36 Figure 3(d) shows the change in link level emissions produced by the combination of
37 corridor VEP and variable demand. Much of the improvement in emission results from VEP and
38 reductions in demand for travel in the county due to the added cost of travel along the 270
39 corridor. Travel costs also increase on arterials and local roads as the cost in time to divert

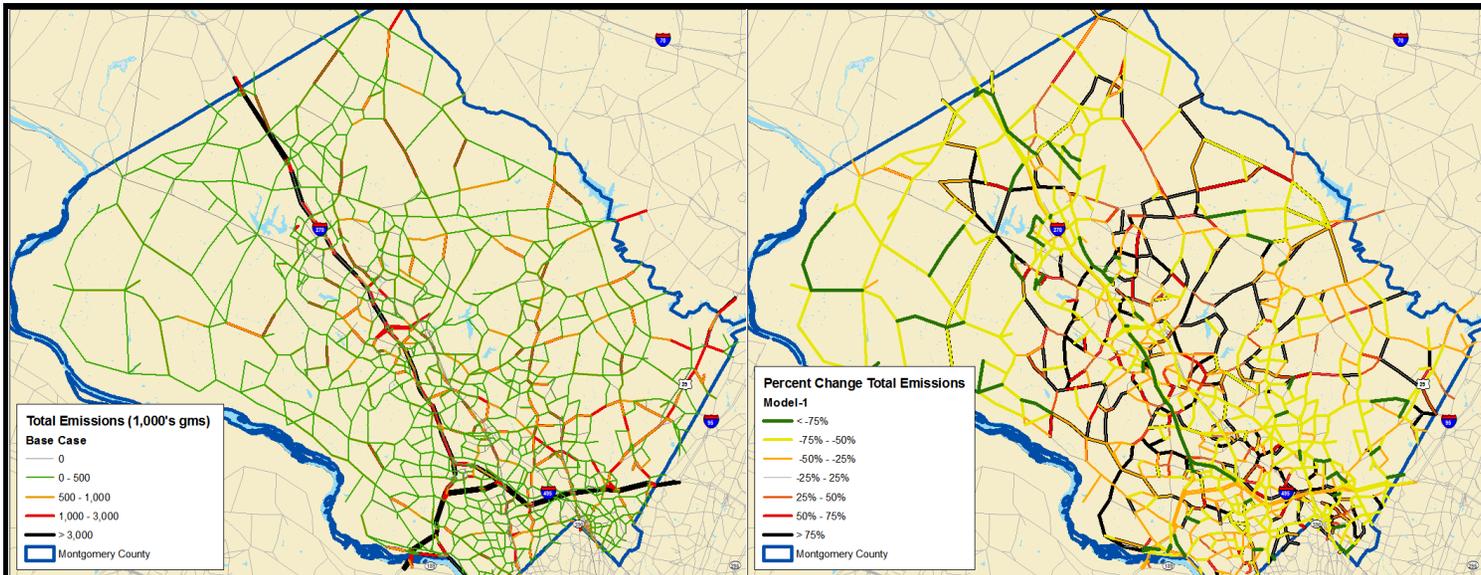

FIGURE 3(a) Total System Emissions Base-Case

FIGURE 3(b) Percent Change in Emissions Model-1

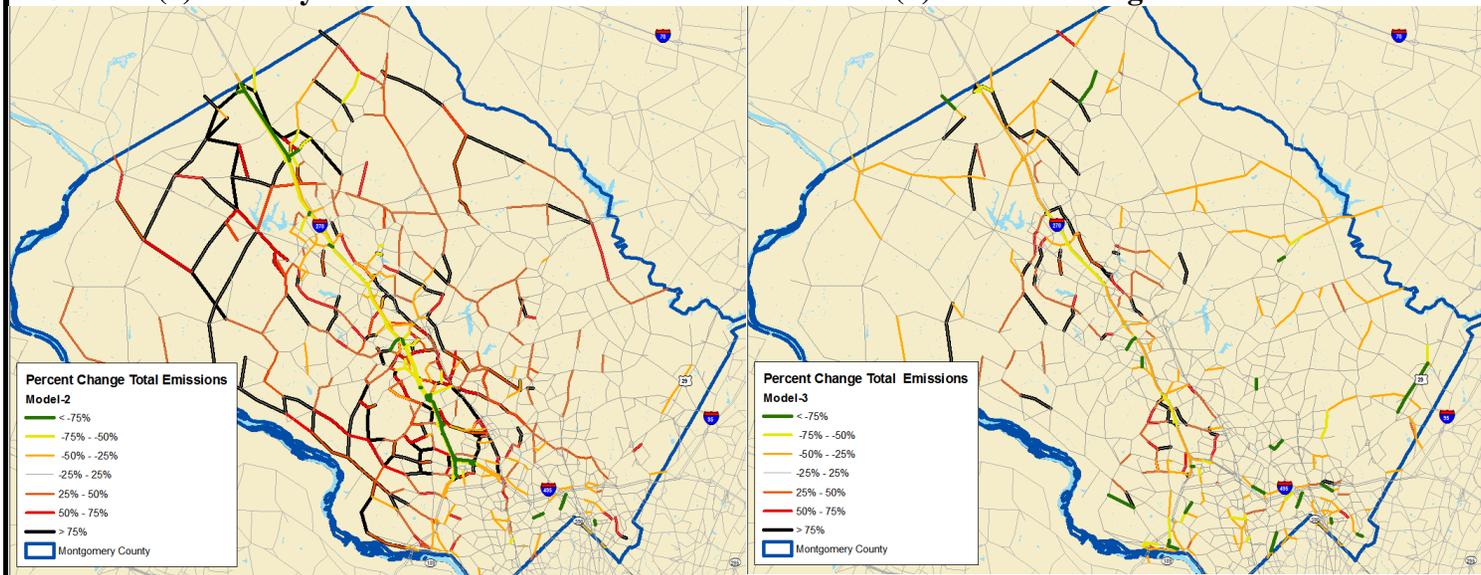

FIGURE 3(c) Percent Change in Emissions Model-2

FIGURE 3(d) Percent Change in Emissions Model-2

1 around the corridor and in fuel expense reduces demand for travel on many roads. Some local
2 roads show an increase in emissions as the cost of travel is comparatively low on these roads and
3 does not increase to a level high enough to reduce total demand for trips. Emissions on the VEP
4 corridor show reductions ranging from 25% to 50% for all links.

5

6 **SYNTHESIS OF MODEL RESULTS**

7 The results for the Base-case and three models are presented in Table 3. Each model result is
8 further broken down by the facility type. The first column of results in the table provide the total
9 system travel time (TST), followed by the total system emissions (TSE) shown in columns (3)
10 and (4). The table also shows the vehicle miles travelled (VMT), average speed, number of
11 congested lane miles (lengths of road with a volume to capacity ratio of over 0.75), and the
12 number of links that are charged (exceed the predetermined cap) that result from each model.

13 In the Base-case TST is 154,453 hours and total VMT is 4,199,854 hours, which results
14 in an average speed of 27 miles per hour. Without any emissions reduction strategies total system
15 emissions for the Base-case are at the highest level compared to the three models. This is in part
16 due to amount of traffic volume on the highways which results in a total of 375 congested lane
17 miles with the majority of those miles on freeways and major arterials.

18 Model-1 shows a 9.6% improvement in TST when each link that exceeds the
19 predetermined emissions cap has VEP applied which is calculated between iterations of the
20 assignment algorithm. The reductions in freeway travel time (57%) and increase in average
21 speed (from 38 to 49 mph) is greatest for freeways, with a modest improvement in major
22 arterials (a 32% decrease in TST and a one mph increase in speed). However there is an increase
23 on minor arterials for TST (59%) and a reduction in average speed (from 23 to 18 mph) and for
24 other roads (38% increase in TST and a four mph decrease in speed). This result is mirrored in
25 the level of emissions (29% and 20% respectively) and number of congested lane miles (124%
26 and 269%). Freeways and arterials show significant improvements in reducing both emissions
27 and congestion while minor arterials and other roads results in an opposite trend. There are two
28 phenomena acting in Model-1 to produce the results. First, the study area is only a small part of a
29 larger transportation network that consists of links outside Montgomery County. As a result,
30 users have a variety of alternative routes to select from when making a trip. When all links are
31 potentially subjected to VEP, it is more cost effective for some users (with a low VOT) to select
32 a route that is outside of the study area, effectively outside the potential VEP area. This produces
33 an overall decrease in VMT and helps reduce system emissions and congestion. At the same
34 time, by setting a target emissions level (cap) dependent on the 50th percentile of emissions per
35 mile, some less travelled roads gain emissions capacity will other congested roads are
36 significantly over capacity. Since the VEP is a measure of emissions over capacity, many of the
37 lower facility types such as minor arterials, collectors and other roads become feasible non-

1 charged routes for users with a lower VOT; in other words, those that can spend the time to go
 2 around the charged links. As a result of this, emissions levels, travel time, VMT and congestion
 3 all significantly increase on these out of the way but cheaper routes.

4 Model-2 demonstrates that the corridor VEP model achieves a lower reduction in
 5 emissions (5% compared to 24% in Model-1) but only initiates a VEP strategy on 88 links
 6 compared to the 1,405 links required in Model-1. Model-2 results in higher average freeway
 7 speeds than the Base-case, providing a 39% reduction in freeway congested lane miles. The
 8 model also shows increases in TST (5%) and an increase over the Base-case total congested lane
 9 miles (20%). This occurs, much like in Model-1, because users find it cost effective to avoid
 10 travel on the VEP corridor and unlike in Model-1 there is no additional emissions charge for
 11 users to select a route that avoids the corridor. Because of the availability of cost effective routes
 12 within Montgomery County users chose major and minor arterials.

* "Other" represents collector and local facility types.

14
 15 Model-3 measures the relationship between emission reduction goals and user response
 16 by implementing a variable demand model along with the corridor VEP strategy. The results of
 17 this combined model show improvement for all indicators and all facility types (except
 18 congested lane miles for minor arterials increases 7%). The improvements occur in part because
 19 of the corridor VEP implemented in this model but also because the variable demand component
 20 of model results in a reduction in the total number of vehicle trips both beginning and ending in
 21 O-D pairs within the study area. In total, there is a reduction in travel demand of over 63,000
 22 vehicle trips for all O-D pairs in Montgomery County which is less than 16% of the 396,500 trips
 23 that would otherwise occur in the county. This reduction in vehicle trips leads to an overall

1 average system speed of 28 mph, which is higher than the Base-case and Models 1 and 2. The
 2 results also show improvement in total congested lane miles which shows a 22% improvement
 3 over the Base-case. In a single instance, on minor arterials, congested lane miles increased. This
 4 model provides a good estimate on how users might react with knowledge about road conditions
 5 and travel cost is known.

6

7 **FIGURE 4 Convergence Results for All Models**

8 To test for convergence the gap (*see Appendix-A*) between assignment iterations in the case of
 9 the Base-case and models 1 through 2 and assignment iterations and loop iterations for model 3,
 10 was measured. Gap is a function of change in assigned link volumes and cost between iterations,
 11 so that as gap decreases the assignment gets closer to convergence which indicates that a change
 12 in travel cost for a link does not produce a significant change in the entire network. For this
 13 paper the convergence criteria was set at a gap of 0.002 for the iterative assignment and 0.005 for
 14 the variable demand iteration. Figure 4 shows the iteration results in terms of the gap for fifty
 15 model iterations. In all cases the models reached the convergence criteria in less than 26
 16 iterations. The three models had computational times per iteration of 12 minutes for Model-1, 8
 17 minutes for Model-2 40 minutes for Model-3. The assignment iteration time varies a result of the

1 emissions model feedback into the assignment algorithm. Model-1 has a longer processing time
2 because more links require emissions calculations. Model-3's computation time was longer
3 because each variable demand iteration has a nested traffic assignment program that also had to
4 iterate and converge. The Base-case and all three models were run in Cube Voyager using multi-
5 core distributed processing in a Windows Server 2008. However the processing times may vary
6 as the computer configuration is altered.

7

8 **CONCLUSION**

9 This paper presents VEP as a tool for emission reduction strategies. A joint travel demand and
10 emission model incorporates the VEP strategies proposed in the paper. The demand model
11 incorporates individual travel behavior in determining the choice of destination, mode and route
12 in response to VEP strategies set by the decision maker. The emissions model, MOVES,
13 developed by EPA is integrated with the demand model for estimation of link based pollutants.
14 Developing such models is complex and involves two major hurdles. First, the difficulty lies in
15 obtaining a certain emission level to model individual driver responses to examine how the
16 targets are achieved. Second, the complexity involved in developing multiple strategies in real
17 world case studies for assisting federal, state and local agencies (or decision makers) to achieve
18 emission reduction objectives. The proposed model addresses both hurdles. First, a robust model
19 formulation is presented incorporating differential VEP strategies. Second, the model is applied
20 to a multimodal transportation network in Montgomery County in Maryland, where the roadway
21 infrastructure connects to the Washington-Baltimore region.

22 A Base-case depicting existing conditions and three models are proposed. The existing
23 conditions are depicted in the Base-case, and emission level is estimated after the traffic
24 assignment. The Base-case resulted in high levels of emissions and led to the development of
25 three models. Model-1 represents a link based VEP suggesting links exceeding a predefined
26 emission level will be penalized. Model-2 demonstrates a practical way of VEP implementation
27 at a corridor level (set of contiguous links) as opposed to link level. Model-3 p more advanced
28 way of analyzing VEP through variable demand, incorporating the willingness to travel
29 component as opposed to the deterministic nature of traffic assignment models. It should be
30 noted that the emission cap is predetermined by the decision maker and the assignment algorithm
31 defines the links in the network to be subjected to VEP in a joint travel demand and emission
32 model. While the Base-case illustrates the existing emission levels, three proposed models
33 provide insightful results in emission reduction.

34 The proposed model has several dimensions of significant impact and contribution to
35 practice. First, development of a functional joint travel demand and emission model to
36 incorporate VEP strategies. Second, procedural development of three models that incorporate
37 decision maker's strategies in emission minimization to examine user's response. Third,

1 application of the proposed methodology successfully to a real world case study to present
2 emission estimates for different policy levels.

3 This paper provides a theoretically robust framework for emissions reduction strategies
4 and further examines user behavior using a joint travel demand and emission model. The results
5 show that through the implementation of VEP, critical emission reduction targets are achievable.
6 While some strategies such as charging all links that exceed a predetermined cap may not be
7 feasible; others that implement VEP along a single corridor show improvements in emissions
8 with fewer resource requirements. The tools developed in this paper offer planners and decision
9 makers a method to test the implications of various emissions policy objectives which is
10 particularly important in the current era of environmental impact awareness. This research can
11 be extended to incorporate uncertainty in travel demand and consequences to emission modeling.

12 ACKNOWLEDGEMENT

13 The authors are thankful to the Maryland State Highway Administration (SHA) for their
14 continued support in the development of Maryland Statewide Transportation Model (MSTM).
15 The tremendous effort by the staff at Parsons Brinkerhoff in the data collection and model
16 development is also greatly acknowledged. The evolution of MSTM is a result of continued
17 research for the last four years at the National Center for Smart Growth Research and Education,
18 at University of Maryland. The research on emission reduction strategies are aimed at
19 development of a real world model that can be used by the state, county and local agencies.

1 Appendix-A: Joint Travel Demand and Emissions Model Algorithm Summary

2
3 **Step 0: Initialization.**

4 Calculate initial demand ($q_{ij}^{c(0)}$) and feasible flow pattern ($f_{ij}^{c(0)}$), based of free-flow
5 travel time. Set (n) = 0.

6
7 **Step 1a: Update.**

$$\text{Set } t_a(x_a) = t_a \left(1 + \alpha_a \left(\frac{x_a}{c_a} \right) \right)^{\beta_a} \quad \forall a; \quad (1)$$

8
9 **Step 1b: Update with variable demand.**

10 Update demand with inverse demand function

$$d_{ij}^{\varphi}(\sigma_{ij}) = d_{ij}^{\tau} \exp(-\omega * u_{ij}^{c(m)}) \quad \forall_{ij,\tau}$$

11
12 where u_{ij}^c is the least cost path between O-D pairs i and j and ω is a positive constant.

13
14
15 **Step 2: Direction Finding.**

16 Find the shortest path

$$u_{ij}^{c(n)} = t_a(x_a) + \frac{\tau_a(x_a)}{\gamma^c} \quad (2)$$

17 Perform all-or-nothing assignment based on updated travel times and obtain auxiliary flows
18 $f_{ij}^{c(m)}$

19
20 **Step 3: Move Size.**

21 Line search for optimal step size, solving for a :

$$\text{Minimize } \sum_a \int_0^{x_a} \left(t_a(x_a, e_a) + \frac{\tau_a(x_a)}{\gamma^c} + \frac{\varphi e_a(x_a)}{\gamma^c} \right)$$

22
23
24 **Step 4: Flow Update with emissions charge.**

25 Find $f_a^{ct(m)}$, $f_a^{ce(m)}$, $f_a^{cn(m)}$ with:

$$u_{ij}^{c(n)}(x_a, e_a) = t_a(x_a, e_a) + \frac{\tau_a(x_a)}{\gamma^c} + \frac{\varphi e_a(x_a)}{\gamma^c} \quad (3)$$

26
27 **Step 5: Assignment convergence criterion.**

$$K \leq \frac{\text{Abs} \left[\sum_{a \in A} \left(f_a^{(n)} * t_a^{c(n)} \right) - \sum_{a \in A} \left(f_a^{(n-1)} * \delta_a^{c(n-1)} \right) \right]}{\sum_{a \in A} \left(f_a^{(n-1)} * \delta_a^{c(n-1)} \right)} \quad (4)$$

28 where K is a dimensionless convergence criterion

29 For Model-1 and Model-2 step 1(b) is skipped. For Model-3, all the steps are executed. If
30 inequality holds, terminate assignment and go to step 1a. Otherwise, set $n = n + 1$ and go to step
31 1.
